Table of Contents

Abstract

In the wake of higher emphasis on environmental consciousness, household power consumption habits will have the most impact on overall energy consumption. The supply-demand chain of energy is dependent on consumption habits in households, through the day, month, and seasons of the year. Electricity use is changing with time as people become more conscious about their carbon footprint, and with more efficient household technology, the consumption rate is changing. On the other end, the government's switch to renewable energy sources makes the supply-demand gap even tighter.

This makes it necessary to analyze the trend of consumption from both a single factor and multifactor perspective that includes temperature, customer price index, electricity prices, and the popularity of energy-saving initiatives. We will build an LSTM (Long Short-Term Memory) Recurrent Neural Network model for the univariate forecasting of power consumption.

We also seek to perform a multivariate analysis with a Temporal Fusion transformer to understand the impact of external factors mentioned above on energy consumption.

Introduction

Power consumption habits may depend on a wide range of factors like electricity prices, social trends through the green initiative, atmospheric conditions like temperature, humidity, precipitation, and overall retail inflation. We plan to study the impact of these factors on power consumption and build a model to predict power consumption based on these factors.

We use MSTL with LOESS for EDA as it decomposes the time series into different seasonal and trend elements, the effectiveness of this decomposition can be identified by the residuals, if they lie within the significant range, the trends have been successfully decomposed by the MSTL.

Since most of the data is in time series, we needed a suitable multivariate model that could handle multiple time series data and capture correlations between them. A random walk model is considered as a baseline for our model, while LSTM and Google's TFT (Temporal Fusion Transformer) performance will be compared and analyzed against this baseline model's performance.

Along with multivariate time series analysis, it is also important to address the granularity of the data that we have obtained, the final model should be able to handle granularity and capture trend and seasonality through hours, days, months, and years. Since we are using multiple data sets with different levels of granularities, like the consumer consumption index which changes every month, we will need the final model to be able to handle multivariate data along with multi-step granularity. These two layers of complexity will provide us with training data that can capture trend and seasonality through multiple time series, exogenous, and seasonal features.

We will compare and contrast the baseline model i.e. random walk with TFT through their accuracy. One ability the TFT model possesses is that it can handle multiple seasonal trends thus addressing the issue of multiple granularity.

We aim to predict and understand the trend in the power consumption habits of households and the significance of factors in the overall trend.

Methodology

Preprocessing

The features that we will use as targets for our EDA and our predictive models include the global active power consumption for an individual household in France as well as the energy consumed via sub-metering 1, sub-metering 2, and sub-metering 3 extracted from a dataset in the UCI Machine Learning Repository, the search trend for the term “ampoules basse consommation” translating to “Energy saving bulb” in French, the search trend for the term “Jean-Louis Borloo” and the search trend for the term “Grenelle de l'environnement” from Google Trends data, monthly consumer confidence survey scores from the INSEE, the price index for consumer electricity and fuel prices from Federal Reserve Economic Data (FRED), the hourly air temperature levels in France and the daily precipitation depth extracted from the Integrated Surface Dataset hosted by the National Oceanic and Atmospheric Administration (NOAA). Our features are derived from multiple data sources, which are merged for this project.

Feature Engineering For Time Series Data

We address outliers and different scaling factors for different time series variables in our data using 2 levels of normalization. We first will transform our values to a uniform scale based on the RobustScaler function via the scikit-learn package. This will be beneficial during exploratory data analysis when we decompose our time series as the RobustScaler function can suppress the influence of outliers during normalization. We still observed outliers in Air Temperature and Wind Speed upon applying the RobustScaler function to their values, we filtered outliers for these features based on a value threshold. We replace values that cross this threshold with NaN before we interpolate for these empty values using spline interpolation.

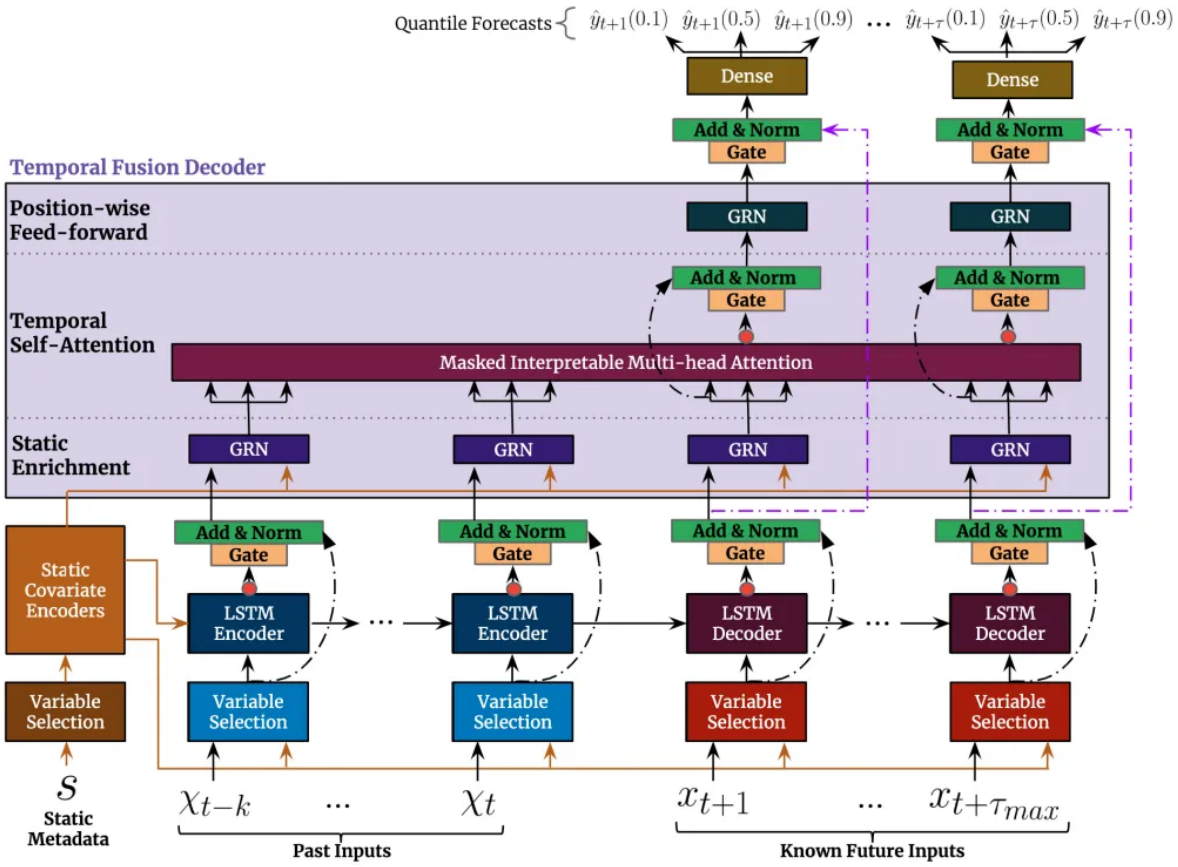
We will use spline interpolation for addressing outliers as well as pre-existing empty values at specific periods in our features. The statsmodel package also offers the MSTL function which decomposes our time series based on multiple levels of seasonality which we will use for our exploratory data analysis to observe seasonal and trend components for each feature.

Temporal Fusion Transformer

The Temporal Fusion Transformer (TFT), is a robust model designed for multi-horizon and multivariate time series forecasting. TFT introduces a predictive approach utilizing past target values, time-dependent exogenous input features, and static covariates. Unlike conventional models providing single-value predictions, TFT generates prediction intervals using quantiles, offering a more comprehensive forecast range.

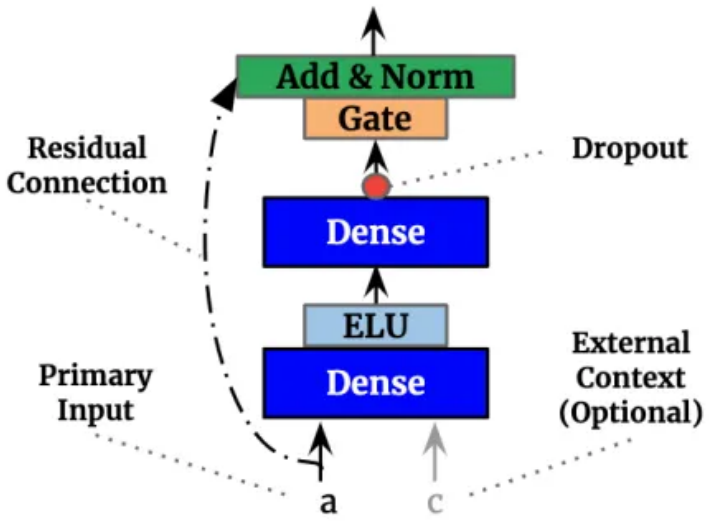
The Temporal Fusion Transformer (TFT) serves as a powerful model for forecasting various time series scenarios. Its predictive capacity leverages historical target values, time-related unknown features, known time-dependent features, and static contextual information to anticipate future trends. This methodology marks a departure from singular value predictions by incorporating prediction intervals through quantiles.

Unlike ARIMA forecasting models, there is no need to make the time series stationary by using log difference transformation, for TFT, the time series can be left as is.



TFT Model Architecture: TFT's architecture comprises distinctive components:

Gated Residual Networks (GRN): Integrated at different levels within TFT, these networks facilitate flexibility by establishing skip/residual connections. Such connections enable the model to bypass unnecessary nonlinear layers, thereby enhancing its adaptability across diverse scenarios and significantly reducing parameter requirements.



Gated Residual Network (GRN)

Static Covariate Encoders: These modules extract context vectors from static metadata, strategically embedding them into the TFT network. This embedding occurs at multiple points, enabling the model to integrate static information into temporal representation learning.

Variable Selection: TFT employs separate variable selection blocks for different input types, determining the significance of each feature. This selective approach enables subsequent layers to process transformed inputs, enhancing the model's ability to learn from continuous and categorical features effectively.

Sequence-to-Sequence Layer: Replacing positional encoding found in Transformers, this layer specializes in capturing local temporal patterns through recurrent connections. Context vectors initialize the LSTM unit, enriching temporal representation with static information.

Interpretable Multi-head Attention: TFT refines the multi-attention mechanism to ensure interpretability. By sharing weights across attention heads, the model facilitates easy identification of relevant values, aiding in understanding past time steps' influence on forecasts and detecting significant changes in temporal patterns.

Quantile Regression: TFT employs quantile prediction, estimating the distribution of target values, allowing for quantification of uncertainty at each time step.

TFT's interpretability features stand out in two primary aspects:

- The ability to trace relevant past time steps for each forecast is traditionally achieved through seasonality and autocorrelation analysis.
- Identification of substantial changes in temporal patterns by comparing average attention patterns per forecast horizon with attention weights at each point.

Google's Temporal Fusion Transformer (TFT) presents a promising methodology for multi-horizon and multivariate time series forecasting. Its interpretability features, variable selection capabilities, and refined attention mechanisms offer valuable insights into understanding temporal patterns and uncertainties in forecasts.

We will use the TemporalFusionTransformer model from the PyTorch Forecasting library and PyTorch Lightning

This process has three steps:

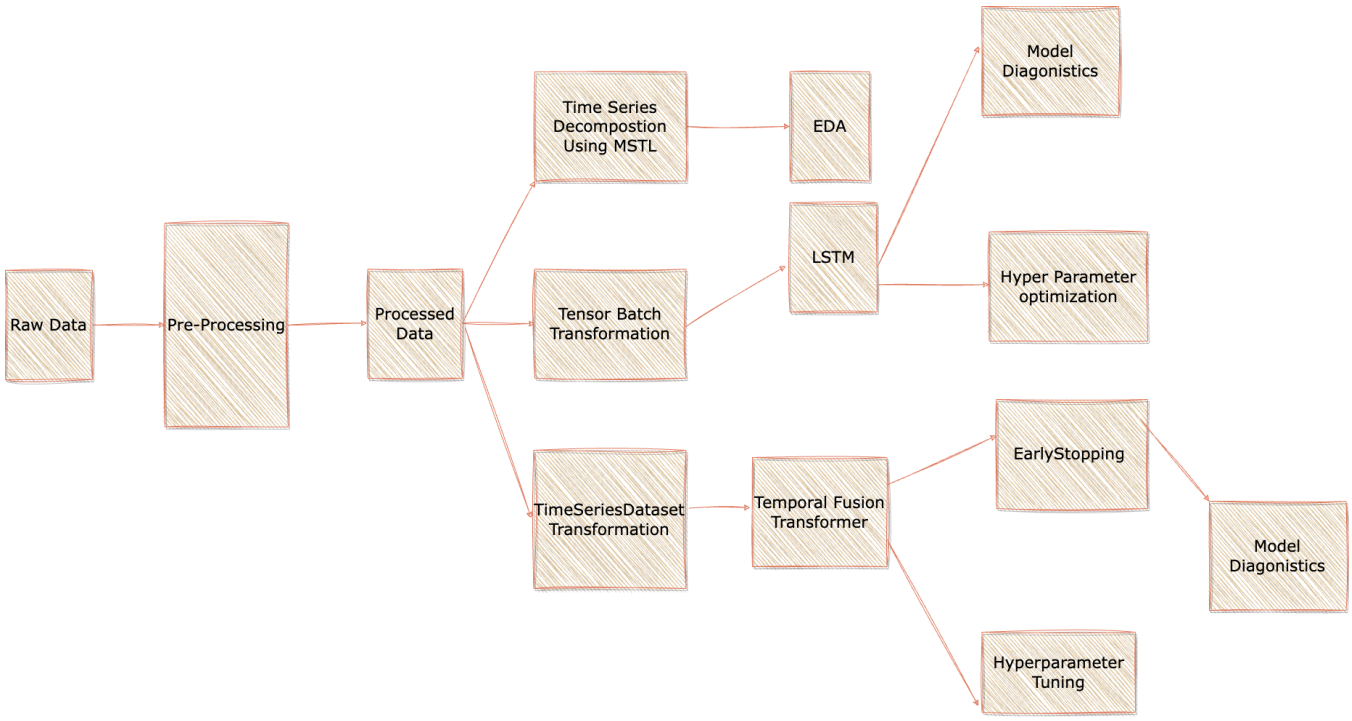
- Wrap our data frame into a TimeSeriesDataset instance.
- Pass our TimeSeriesDataset instance to TemporalFusionTransformer.
- The TimeSeriesDataset is very useful because it helps us specify whether features are time-varying or static. The TemporalFusionTransformer accepts only this format for processing.

Apart from all other parameters, the most relevant for our project will be ‘max_encoder_length’ which defines the lookback period, and max_prediction_length which specifies how many data points will be predicted.

We do not have to write our own Dataloader as the TimeSeriesDataset format will handle the features, and allow for easy normalization of the sequences as they will differ in magnitude, i.e. CCI is released monthly. The GroupNormalizer is used for the task. We also can specify a lookback window for predictions, this is set according to the granularity of our base data, that is hourly and one week prior.

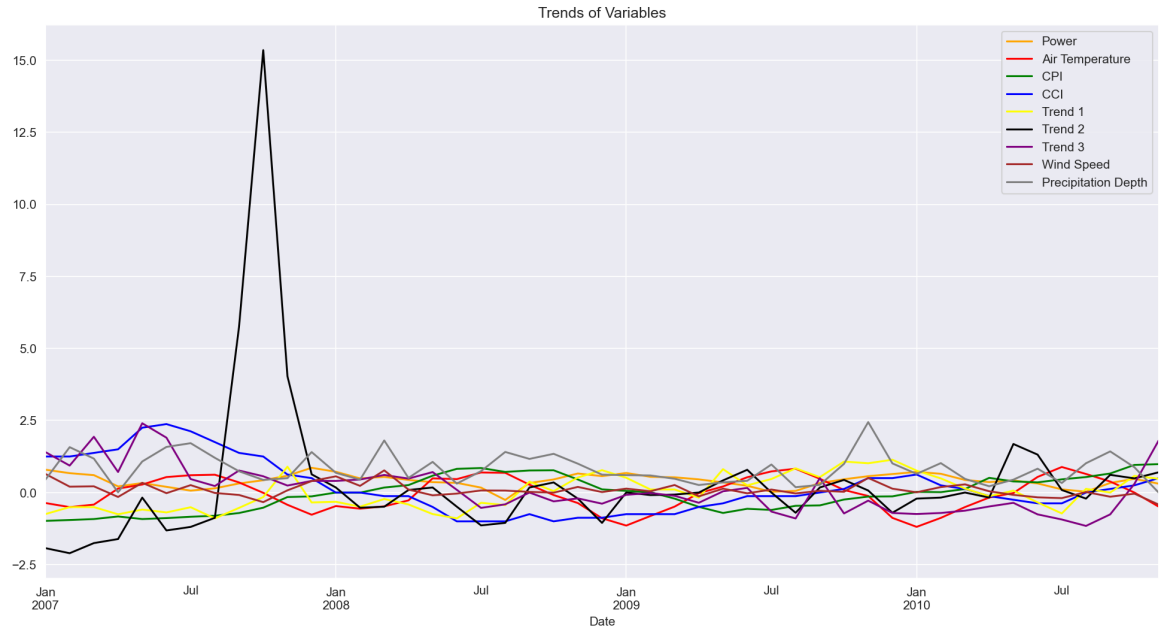
We use the EarlyStopping callback to monitor the validation loss. We use Tensorboard to log our training and validation metrics. Our model uses Quantile Loss - a special type of loss that helps us output the prediction intervals.

Pipeline



Exploratory Data Analysis

Overlay Charts



The constructed overlay charts display the normalized trends of the time series variables - global active power, sub-metering 1, 2, and 3, air temperature, CCI score, CPI index, the 3 search terms, wind speed, and precipitation depth.

In the overlay chart that tracks the time series from January 2007 to November 2010, we take note of a significant peak in the second Google search term corresponding to “Jean-Louis Borloo”. Jean-Louis Borloo references an individual who was the Minister of Ecology, Energy, Sustainable Development, and the Sea for France from 2007 to 2010. It is possible to attribute this spike to the popularity of the “Grenelle de l'environnement" which took place during the summer and fall of 2007 that Jean-Louis Borloo had participated in.

The remaining normalized features have relatively similar levels of peaks and dips. We will examine this relationship further in our next section.

Time Series Decomposition using MSTL with LOESS

For our exploratory analysis, we will decompose the time series of our variables into their level, trend, seasonality, and residual components. An additive time series model can be represented in the following equation as shown:

$$y(t) = \text{Level} + \text{Trend} + \text{Seasonality} + \text{Noise}$$

An additive time series model is when the components of the time series are added together and is commonly used when the seasonality component is relatively constant concerning trends. A multiplicative time series model can be represented in the following equation as shown :

$$y(t) = \text{Level} * \text{Trend} * \text{Seasonality} * \text{Noise}$$

A multiplicative time series model multiplies the components of the time series together and is used to represent time series variables with seasonal fluctuations that have varying amplitudes over time concerning trends, and it differs from the additive model in the relationship between the components of the time series. We will utilize the MSTL package from the stats model, which allows us to measure multiple levels of seasonality within a time series. All our variables exhibit fluctuations that can be modeled by an additive time series model. MSTL utilizes the LOESS (locally estimated scatterplot smoothing) which is a non-parametric regression technique that extracts 3 components, the trend, the seasonality, and residuals from a time series feature.

Appendix B of our Appendix section will contain the output graphs of the MSTL function applied to all the features displaying the trend and seasonality component. We also show magnified views of seasonality components based on a filtered period, and the Python code used to build our visuals and analysis.

The global active power consumption of the specific household aggregated to the hourly frequency, can potentially exhibit 3 levels of seasonality (Visual A). One on the daily level where seasonality patterns exist within a day (Visual B), the weekly level within days of the week (Visual C), and the yearly level where seasonal patterns exist within months of the year (Visual D). The trend, adjusted for all levels of seasonality, is shown to exhibit a downturn in late 2008 to early 2009 before rebounding to a lower average level in mid-2009 until 2010. We will discover as we move forward that dips in level during late 2008 are also seen in weather data. When we focus on the daily seasonality component from global active power, we see that power consumption peaks during midday hours around 12 PM, and drops down to its lowest point around 8 PM. January 1st, 2007 starts on a Monday. The weekly seasonality shows that most power is consumed during weekend hours, which could be explained by the individuals in the household having no work during the weekends which causes more power consumption due to spending longer hours at home. Power consumption is also shown to have a yearly seasonality pattern, where it shows a steadily decreasing trend from January to August before an upshoot from August to December. This could be explained by a greater need for heating and electricity during the Fall and Winter months, August through December in France are shown to have relatively lower levels of air temperatures as we will examine for our next feature.

Air Temperature data recorded in France on an hourly level, is also seen to show strong seasonality within daily and yearly levels (Visuals E and F). Air Temperature is shown to spike during midday hours within a day. On the daily level of seasonality for Air Temperature with hourly frequency, the air temperature is at its highest at noon, before it drops to its lowest between 10 PM and 11 PM. It also peaks during the first quarter of the year before a consistent decline throughout the year. The seasonally adjusted trend (Visual G) shows a consistent

increase in the temperature level over the period from 2007 to late 2010, with minor dips during the last quarter of 2008 and the last quarter of 2009.

For time series that are of monthly granularity such as the CCI score and CPI index, they can exhibit a single level of annual seasonality shown (Visual H and I). For CCI, the yearly seasonal behaves in a pattern that repeats from 2007 to 2009, with consumer confidence scores regarding economic outlook peaking during the first to second quarter of the year and dropping off from around the mid-year to end of year. The seasonal component breaks from this pattern from 2009 onwards until late 2010, as it experiences a downward trend within the first few months of the year before experiencing a general upturn until the end of the year.

The CPI score which tracks the price index of consumer electricity and fuel prices exhibits a constant seasonality pattern that repeats yearly from 2007 to 2010. The yearly seasonality component indicates that August shows the lowest CPI index in the year which means that the consumer price levels of electricity and fuels are at their lowest during this time before peaking in the final quarter of the year around November. The price index was the highest during mid-2008, before dropping off in mid-2009 and rebounding in 2010. There are possible economic implications that can be attached to the behavior of CPI and CCI scores, regarding the economic recession that spanned from late 2008 to 2009.

All 3 search terms have a weekly frequency and therefore can exhibit 2 levels of seasonality which are monthly and annually. The first search term (Visual J) which tracks “Energy saving bulb” experiences an upturn and peaks around mid-2009 before gradually decreasing which shows that there was the greatest interest for terms related to energy-efficient appliances such as light bulbs during that period. The second search term (Visual K), which is the name of the Minister of Ecology, Energy, Sustainable Development and the Sea in France, experienced a surge in popularity from early 2007 to January 2008 before dropping down to a lower average level in mid-2008 before experiencing a rebound around April 2010. The third search term is the keyword “Grenelle de l'environnement” (Visual L). The popularity of the search term shows a consistent decline from early 2007 until late 2010. The initial high popularity of “Grenelle de l'environnement” is attributed to the event taking place in the

summer and fall of 2007. The search term therefore gradually lost popularity possibly due to less media coverage upon completion of the event. The 3 search terms share a similar monthly level of seasonality with a cyclical pattern throughout one month (Visuals M, N, and O). The first search term denoting “Energy saving bulb” tends to dip during the first 2 weeks of the month until it peaks towards the end of each month as shown in the weekly seasonality plot. The other 2 search trends for “Jean-Louis Borloo” and “Grenelle de l'environnement” also display a similar pattern within a monthly cycle based on dips early within the month followed by rebounds from the second half onwards. The yearly seasonalities can also be found (Visuals P, Q, and R). The first search term shows a general decline from the start of the year until mid-August where we see large increases towards the end of the year. The second search term also shows a strong spike towards the end of the year around November, scaling off before January which means that interest in terms related to Jean-Louis Borloo is highest around November before steeply dropping. The third search term shows spikes during the mid-year before decreasing towards the end of the year.

We can draw insights from the household’s electricity consumption patterns when total energy consumption is dissected into portions that represent everyday functions within the household. Sub-metering 1 (Visual S) corresponds to the active energy consumed in appliances located in the kitchen of the household mainly for cooking, heating, and baking purposes. Sub-metering 2 (visual T) corresponds to the energy consumed in the laundry room, and Sub-metering 3 (visual U) corresponds to the combined energy consumption within an electric water heater and air conditioner. The active energy consumed on the daily level (Visuals V through X) for sub-metering 1 drops dips at 10 AM, before rising at 11 AM. Other notable peaks in the day include 4 PM and midnight. Sub-metering 2 peaks at 1 pm and 5 pm, and has the steepest decline during midnight on a daily level. Sub-metering 3 has notable dips at 9 AM, and peaks again at 5 PM and 7 PM. On the weekly level (Visuals Y, Z, and A1), the 3 features share a common trend as we see shared peaks around Sunday with relatively higher levels of energy consumption during the period as compared to the rest of the week. The 3 submetering trends also have yearly patterns. (Visuals A2, A3 and A4). Sub-metering 1 and 2 show cyclical patterns throughout the year with continuous spikes and dips in level across the period. The yearly pattern of sub-metering 3 more closely

resembles that of the household's global active power as it peaks towards the end of the year. The seasonally adjusted trends for Sub-metering 1 show that it has decreased consistently throughout the period from 2007 to late 2010. Sub-metering 2 also exhibits a similar downturn but the trend stagnates around early 2009. Sub-metering 3 on the other hand shows a positive trend, as we see a sharp upturn until it stagnates in late 2009 to early 2010.

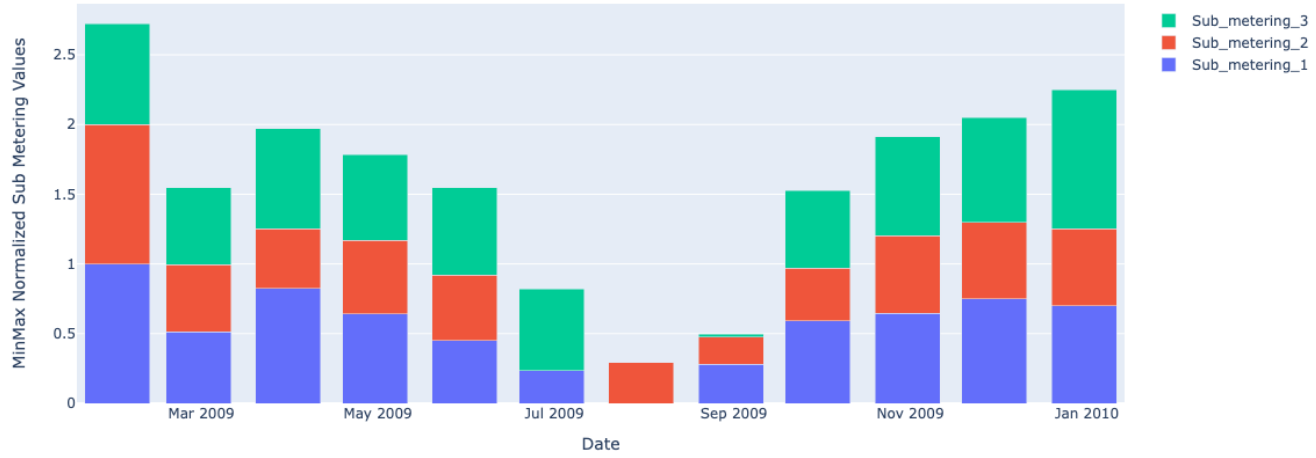
The wind speed is defined as the rate of horizontal travel of air in meters per second. The wind speed is shown to exhibit the highest levels on average during 5 PM within a day, whilst it drops to its lowest points during odd hours of 12 AM to 5 AM (Visual A5). The wind speed shows an upturn with cyclical patterns until September where it starts to decline until the end of the year, before rebounding into another peak (Visual A6). This tells us that the relevant region in France has relatively windier months from September to December. The wind speed over the period from 2007 to 2010 has shown to have upturns and then points of the plateau before dropping off, one in late 2008 and one in early 2010 (Visual A7).

Precipitation depth measures the total amount of rainfall within 24 hours distributed evenly over a watershed area. The precipitation depth started to show a steep decline in its seasonally adjusted trend around the middle of 2008 (Visual A8), which gives the inference that rainfall during this period was relatively lower than the other periods before seeing a rebound from the middle of 2008 onwards. The precipitation depth is shown to exhibit cyclical levels of seasonality throughout the year (Visual 8). There are many peaks across the year, with the most notable peak being towards the end of the year in early December before dropping off rapidly. Similar to wind speed, the seasonally adjusted trend of precipitation depth also varies across the period and does not display stationarity. The recorded precipitation depth had seen a strong downward trend from late 2008 onwards until mid-2009 before increasing to a higher level until the end of the period in 2010 November. From this trend, we see that the period from late 2008 to the second quarter of 2009 displays abnormal behavior. The dip in precipitation depth coincides with the plateau in wind speed and a dip in air temperature during the last quarter period of 2008. This potentially suggests that the period in question shows relatively lower levels of rainfall, wind, and temperature as compared to other periods when adjusted for seasonality.

Extrapolating the previous insight onto our aforementioned analysis on the global active power consumption and sub-meterings shows that amid this dip in weather metrics, the power consumption also declined during the same period of late 2008. We can assume that this decline is correlated with the decline in energy consumption in sub-meterings 1 and 2, which correspond to electricity use in the kitchen and laundry room respectively during the same period. There are potential socioeconomic connections we can draw to explain this behavior, shown by the CCI score which is an indicator that reflects the general economic outlook of households in France. The CCI score also saw a large decline in the last quarter of 2008 which we can interpret as a more negative economic outlook.

It is important to examine the residuals in each feature's time series decomposition, to gauge for the independence and randomness of the residuals. Independent residuals are residuals that show no serial autocorrelation, and this means that the MSTL model was able to exhaustively extract all trends and seasonal components from the time series. Residuals that show serial autocorrelations, give us the inference that there are still underlying trends additional to the pre-existing ones in our time series that we can still discover through more sophisticated techniques, which will be beyond the scope of this paper. The Durbin-Watson statistic is a statistical test that can check for the presence of serial correlation in the residuals of a regression model. The null hypothesis is defined to be that first-order autocorrelation does not exist within residuals whereas the alternative hypothesis is that first-order autocorrelation exists. Values for the Durbin-Watson statistic range from 0 to 4. Values that are below or greater than 2 are likely to have some level of autocorrelation, with values lower than 1 or greater than 3 showing significant likelihood of autocorrelation. In our data frame of test results for each feature (Visual A9) we see that when we apply the test via the stats model package to our features' MSTL residuals, there are several features that exhibit a high likelihood of autocorrelation. The features are global active power consumption, sub-metering 3, CCI score, CPI index, the second search term "Jean-Louis Borloo", air temperature, and precipitation depth. We conclude, therefore, that given that we have extracted and analyzed the trend components and multi-seasonality patterns for arbitrarily defined seasonality levels, there is the possibility of uncovering additional trends and seasonality beyond what we have explored in the paper.

Stacked Bar Graph



The three submetering levels represent different types of appliances that consume electricity:

- Sub Metering 1 - Appliances in the Kitchen, such as a dishwasher, an oven, and a microwave.
- Sub Metering 2 - Washing Machine, Tumble Dryer
- Sub Metering 3 - Electric water heater and an Air Conditioner

The above-stacked bar graph shows the monthly sums of the three sub-metering levels. Since the watt-per-hour consumption of every metering cannot be scaled on the same graph due to a large difference in the sums, we have used min-max normalization for visualization purposes.

From the graph, it is clear that the submetering levels have a yearly trend and change according to the weather seasons. The months with moderate cold and heat show decreased submetering for level 3, i.e. air conditioning and heater as the moderate weather does not require additional air conditioning or heater use. January and February show the highest consumption of electricity for all the submetering levels, this may be due to the holiday break when most people have returned to their normal schedule and the weather is at its coldest.

During July and August, The submitting levels 1 and 2 have also shrunk, this may be due to the vacation season and people not being in their households to consume electricity.

Since the datasets take into account a particular household, the negligible consumption in August for all three sub-metering levels indicates that the household was unoccupied during those months. Overall, the three sub-metering levels reflect power consumption through habits through the seasons and this can be explained by the weather at that time.

Dataset description

Power Consumption: Individual Household Consumption Dataset (UCI) - This dataset contains data from one household and includes the following fields: Date, Time, Global Active Power, Global Reactive Power, Global Intensity Voltage, Sub Metering 1, 2 & 3.

Integrated Surface Dataset for Daily Weather Data (NOAA): This dataset contains synoptic surface information from numerous weather stations. We use the hourly air temperature in degrees Celsius recorded by a weather station in Abbeville, France. (a 2-hour drive from Sceaux, where the household is located), daily precipitation depth in meters, and hourly wind speed in meters per second from January 2007 to November 2010.

Monthly CPI: Electricity, Gas and Other Fuels for France (FRED) - reflects the monthly electricity prices from 2007 to 2010

CCI: The monthly consumer confidence index (CCI) by INSEE is an indicator based on a consumer survey conducted on households in France. The survey aims to explore general attitudes regarding economic outlook through the lens of expenditure and saving habits. The dataset contains monthly CCI scores from January 2007 to November 2010.

Google Trends: We have selected three terms related to policy changes and popular green energy efforts that may have affected the power consumption habits as shown below

File Name	Term	Meaning
GoogleTrends1.csv	ampoules basse consommation	Energy saving bulb
GoogleTrends2.csv	Jean-Louis Borloo	Minister of Ecology, Energy, Sustainable Development and the Sea
GoogleTrends3.csv	Grenelle de l'environnement	The 'Grenelle de l'environnement' was an open multi-party debate that took place in France in the summer and fall of 2007 to define key points of public policy on environmental and sustainable development over the following five-year period.

Data cleaning

Like every dataset, out of the six we have chosen, three of them, power consumption datasets, CCI datasets, and weather datasets have some missing values. Since the data is in a time series, we have the option to fill in missing values by using spline interpolation. Spline interpolation involves creating a smooth curve that passes through given points by using piecewise-defined polynomials. Spline interpolation offers smoother results than other methods due to its continuity and differentiability properties.

The spline interpolated values do not influence the trend of the time series and they are based on the adjacent values and the overall trend, thus this provides for a smooth estimate of the missing value. The datetime column of every dataset needs to be formatted in the most readable, consistent date time column through all the six datasets, pandas have a 'to_datetime' function for converting any string value to datetime for any format.

```
df['DATE'] = pd.to_datetime(df['DATE'],format="%Y-%m-%d")
df2010['DATE'] = pd.to_datetime(df2010['DATE'],format='%Y-%m-%dT%H:%M:%S')
df['timestamp'] = pd.to_datetime(df['timestamp'],format='%Y-%m-%dT%H:%M:%S')
```

Model Building and Training

Data Preparation for TFT

Power consumption data such as global power usage, and sub-metering 1,2, and 3 are resampled with seasonality every 6 hours. Other hourly data such as wind speed, precipitation depth, and air temperature are also aggregated based on averages to match the level of the seasonality of power consumption. Values that are of a higher level of seasonality such as CCI, CPI, and Google search trends are converted to 6-hour intervals through forward-filling the monthly values to be constant within datetime periods during the month.

The TFT model requires that we define time indexes within our dataset. We specify the time-varying known categorical variables to be the day, week, month, hour. These are columns we create based on the Date column to specify categorical inputs known into the future. We define the time-varying known reals to be time index and year as they are numerical indexes. Time-varying unknown reals are defined to be time series features that are not known into the future, these variables are our time series features in question. Power consumption globally and for the 3 sub-meterings, CPI Index, CCI Score, the 3 Google search trends, and weather data. Since some of our time series features have a weekly level of seasonality, we set one week as the minimum lookback period and a year as the maximum. The model will utilize past information from within the aforementioned period, to predict global power consumption 6 months into the future as a maximum. These parameter values, along with others, are set in the TimeSeriesDataset class for the conversion of our dataset. This can also be found in the appendix.

Hyperparameter Tuning

The hyperparameters to be tuned in the Temporal Fusion Transformer are the hidden size units, continuous hidden size units, dropout rate, and learning rate. The hidden size units denote the dimensionality of the hidden states within feedforward neural networks in the GRN unit. The continuous hidden size shares a

similar interpretation but is for static inputs. The dropout rate is the proportion at which the neurons in a neural network layer are made to have their output values set to zero. The dropout rate influences the impact of overfitting through this mechanism as it allows for generalization. In the context of the Temporal Fusion Transformer, the dropout rate refers to the dropout layers within the GRN unit. The learning rate is defined as the rate at which the model's weights are updated after each iteration. It can be considered to be the step size during the loss optimization process of the Temporal Fusion Transformer.

We utilize the PyTorch tuning class to access the optimize_hyperparameter function, as well as the optuna package as PyTorch utilizes optuna to iterate through studies, which each contain a collection of hyperparameter combinations that are to be set during loss optimization to gauge which combination provides for optimal results. We optimize against the Quantile Loss function.

The Quantile Loss function is defined as the following: Machine learning models work by minimizing (or maximizing) an objective function. An objective function translates the problem we are trying to solve into a mathematical formula to be minimized by the model. As the name suggests, the quantile regression loss function is applied to predict quantiles. A quantile is the value below which a fraction of observations in a group falls. For example, a prediction for quantile 0.9 should over-predict 90% of the time. ("Blog: Quantile loss function for machine learning")

Results

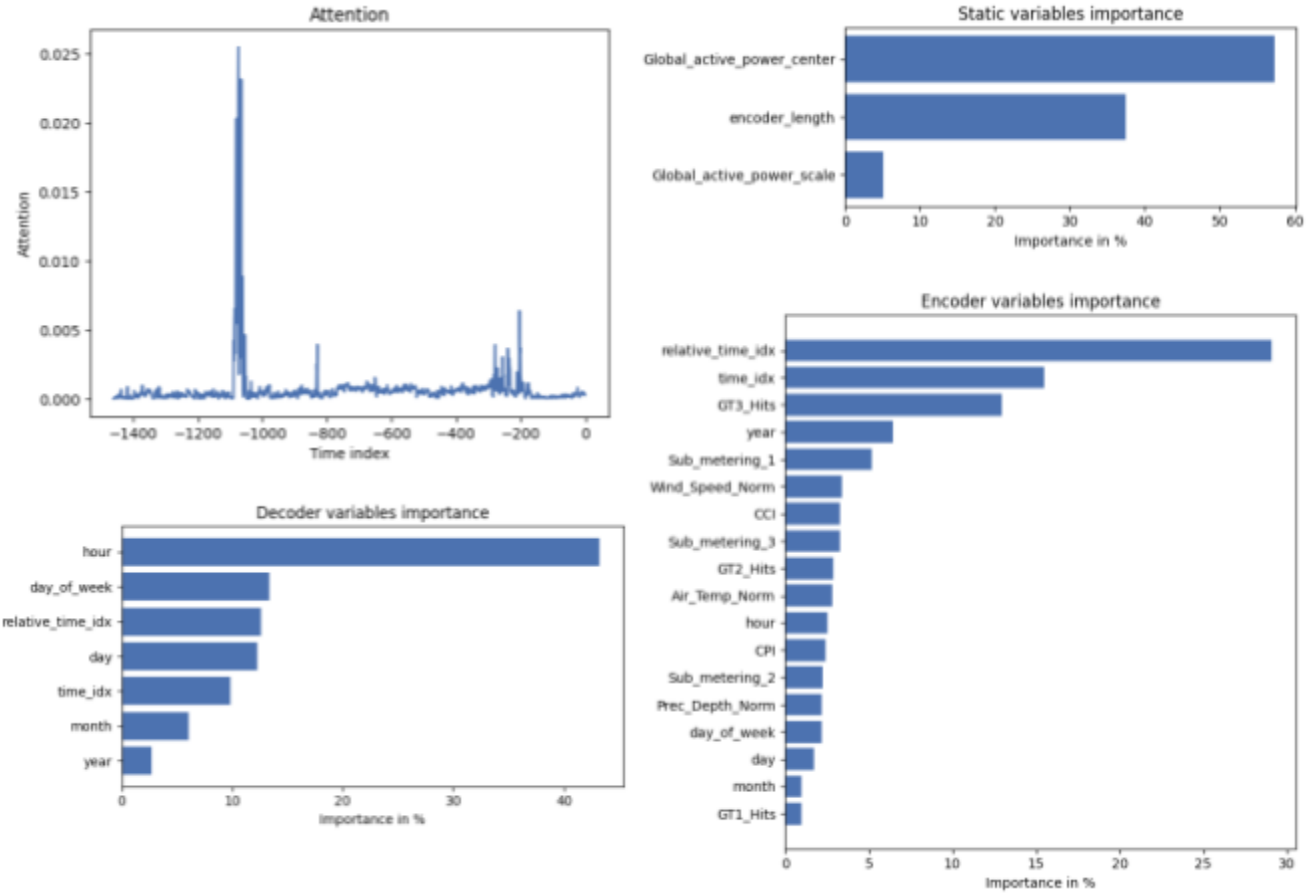
Loss functions

Loss Function - Points	TFT	Baseline
MAPE (Mean absolute percentage)	0.996	1.760
SMAPE (Symmetric mean absolute percentage)	0.675	0.729
Poisson Loss	3.187	3.587
Quantile Loss	0.953	1.001

Table : Comparison of TFT and Baseline on various loss functions

Various Loss Functions show the TFT performs much better than the Naive Bayes-based baseline model.

Variable importance



Observed vs Predicted

The TFT model has multiple prediction formats - raw, data frame, and prediction. Using the ‘raw’ we plot the quantile results of the predictions to the observed values. The raw prediction mode also provides the attention score of the TFT for the relative time index.

Using 'raw' predict mode

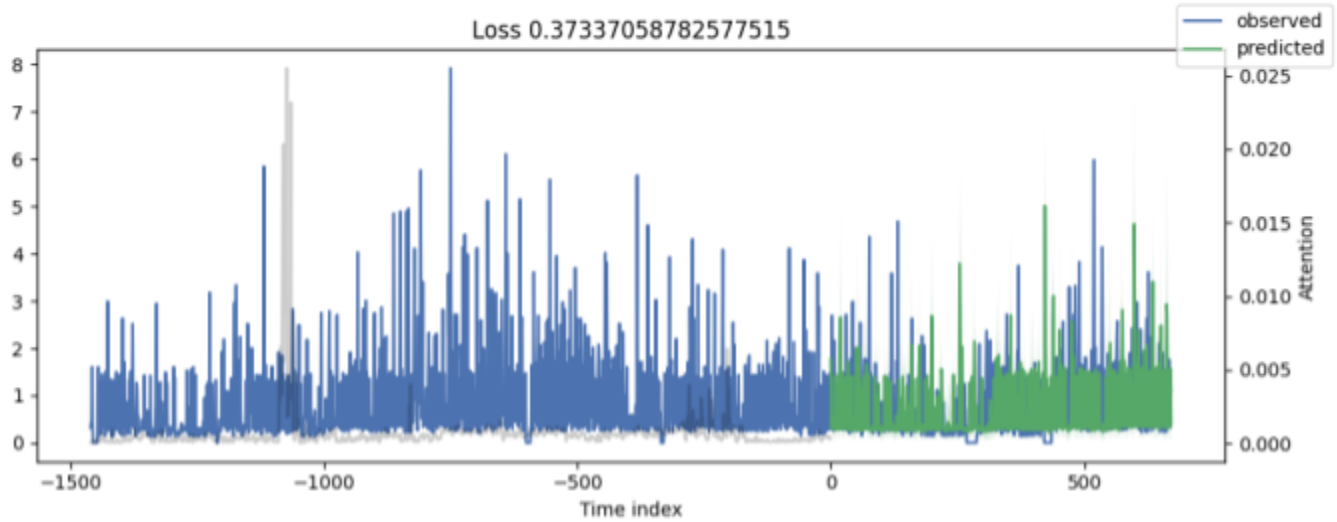


Figure 3.1 Observed vs Predicted Using four years for Hourly Predictions for a year (Grey line indicates attention score during training)

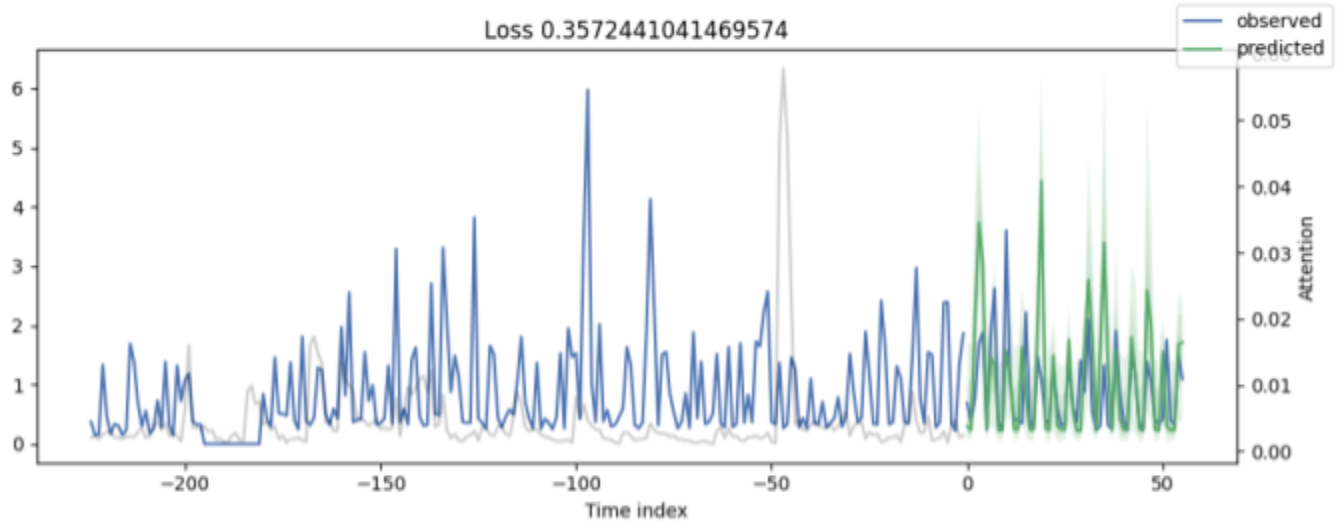

Figure 3.1 Observed vs Predicted Using one month for Hourly Predictions for a week (Grey line indicates attention score during training)

Using 'prediction' mode

Sub-Metering Levels:

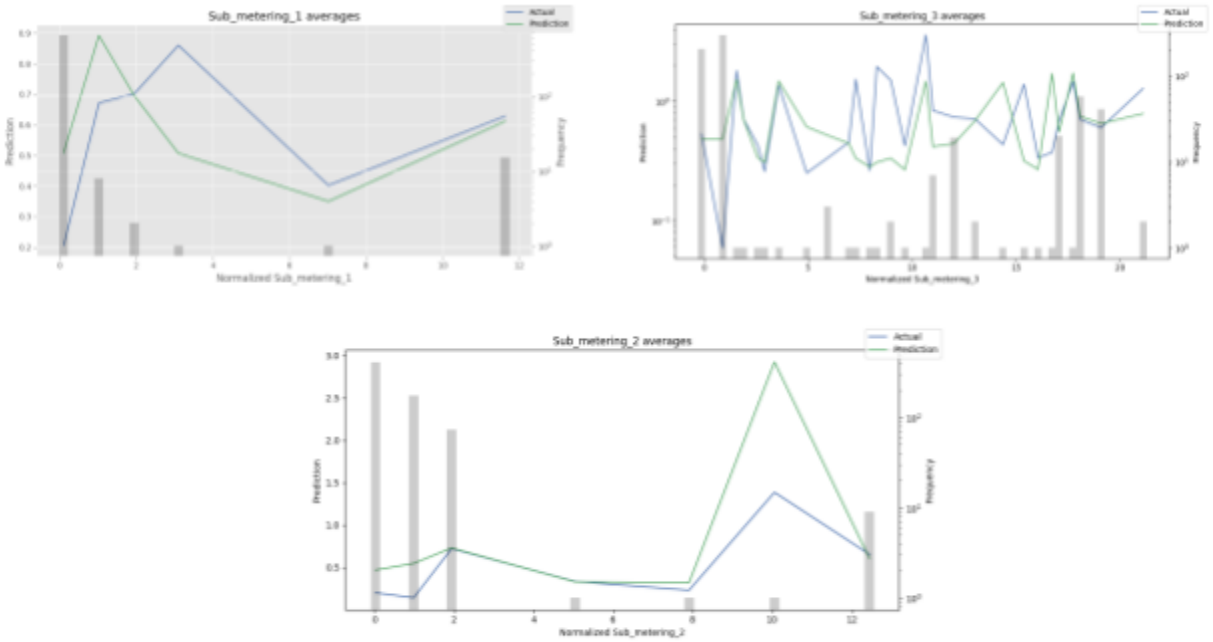

Figure: Observed vs Predicted for Sub Metering 1(top left), 3(top right), 2(bottom)

The submetering levels show similar moments in the line graph above, The magnitude of the y-axis is drastically different, however, the slope, rises and dips are well-tracked by the model.

Weather:

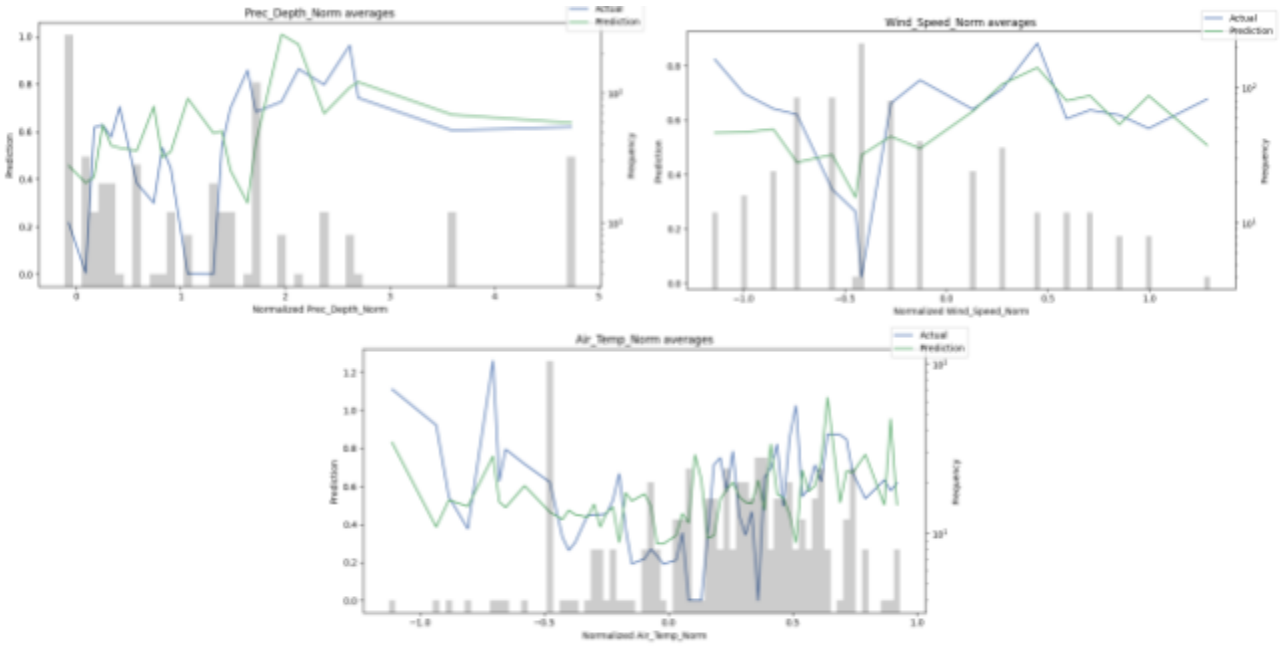

Figure: Observed vs Predicted for Precipitation(top left), Wind Speed(top right), Air Temperature(bottom)

The model fails to predict accurately the air temperature, wind speed, and precipitation rate, there may be various reasons for this including location issues of the household and the weather station. Overall, the model predicts the correct magnitude of the y-axis. The grey bar indicates the attention score by the TFT model, which is consistent as the transformer is unable to correlate the weather trend with global active power.

Google Trends:

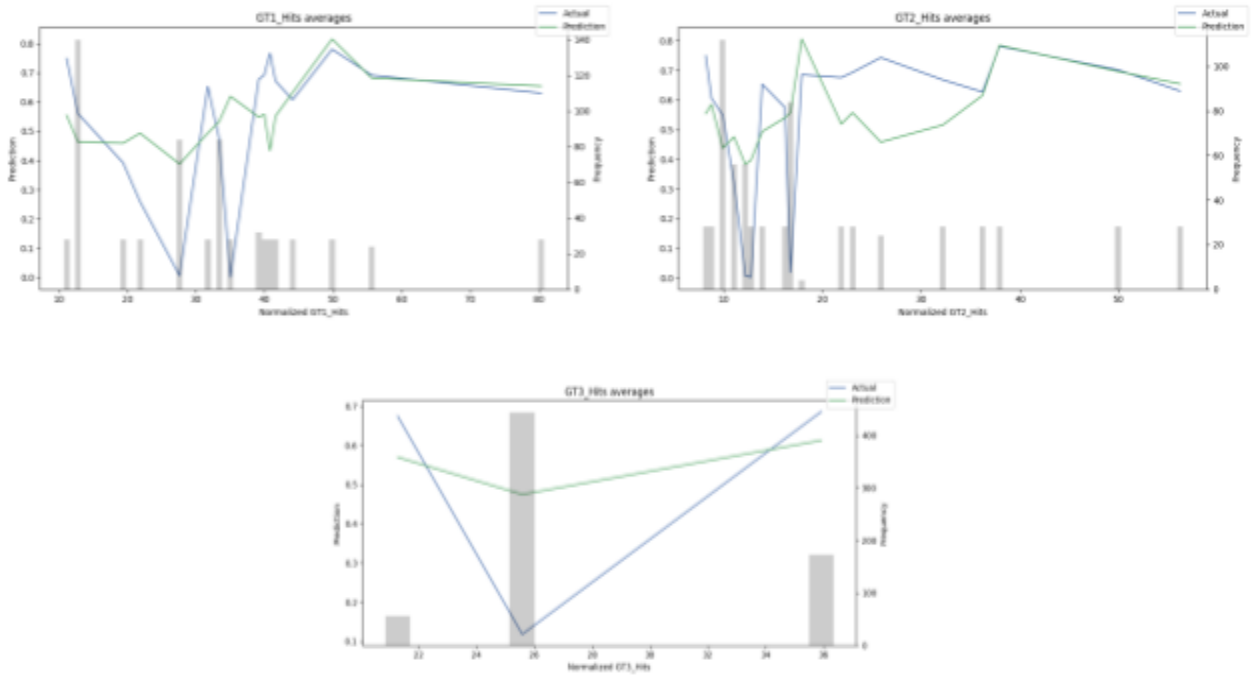

Figure: Observed vs Predicted for Google Trends 'energy saving bulb'(top left), the energy minister(top right), green energy movement (bottom)

The model can assign a high attention score during the peaks and dips of the Google trends, the model does catch up on understanding the magnitude of the trend. Thus, the model can effectively amalgamate the weekly Google Trends to predict hourly Global Active Power.

CPI and CCI:

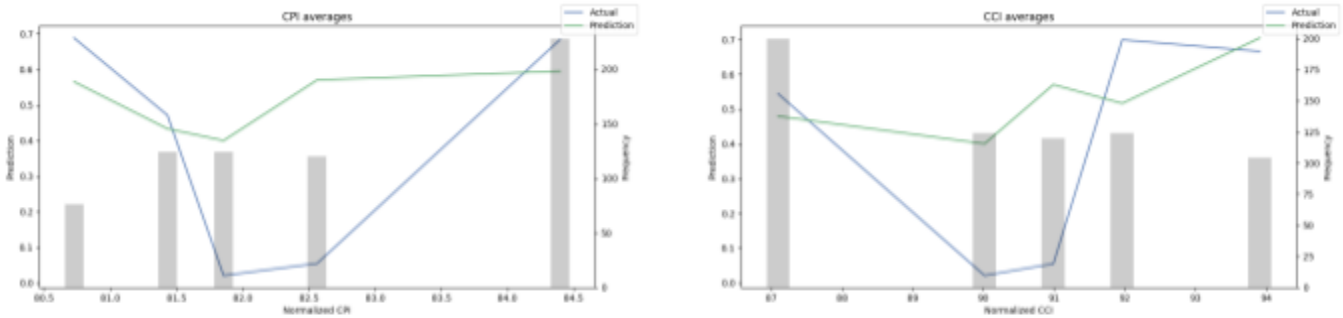

Figure: Observed vs Predicted for CPI(left), CCI(right)

Conclusion

The most significant variable in detecting the global active power for the next hour is the hour (categorical) and relative time index. Since we had considered four points of time in a day, it was found that the global active power for that particular hour is dependent on which point of time it is during the day and the relative time index i.e. the index number of the reading.

The weekly features like Google Trends have significant importance and the Temporal Fusion Transformer can utilize these to make predictions, the TFT is also able to understand the impact of these features over different granularities. Google Trend 3 has the most importance among the features. The monthly features i.e. CPI and CCI have a relatively low impact on the global active power prediction.

The three weather features i.e. precipitation rate, wind speed, and air temperature have low to no correlation and importance to the prediction of global active power. The weather features have the same hourly granularity as the global active power, however, the model does not utilize these features for prediction. A lag is also observed between the predictions and actuals for the above-mentioned three features, this may be due to relevant weather features existing at other points in time other than the ones considered. The location of the weather station might have significantly different weather than the household considered for electricity consumption.

Thus, the TFT can comprehend and predict temporal features across granularities and can utilize static, categorical, and numeric inputs. The TFT also allows for easy interpretation of the model using variable importance graphs and feature-wise prediction graphs. The TFT allows us to illustrate the attention of the model while training, this tells us more about the influential points and how the model learns and improves.

Limitations

The Temporal Fusion Transformer proved computationally expensive as the optimizing algorithm used 200 compute units on Google Collab Pro to output the hyperparameters after 5 trials.

The lag seen in weather predictions may be due to the weather station collecting data from a location away from the selected household. The lag indicates that weather follows the household after some time from the weather station. There might be a mismatch between the location of the household and the location of the weather station where both might have different weather.

Various loss functions like Multivariate distribution loss cannot be compared against the baseline, as temporal models that predict quantiles are not currently available apart from TFT. Also, the functions available for loss calculations are not robust and lack attributes to exclude and include certain conditions.

Since the TFT can handle multiple targets, there needs to be prediction and output functions designed to handle multiple normalized targets. The output functions for graphs also cannot robustly handle multiple normalized targets. There are also limitations of the Dataloader with normalizing the targets.

Future Work

The predictions of a large set of households can help determine the general power consumption habits and predict the energy needs of households during peak time, vacation, and holiday seasons.

In countries with acute electricity shortages, a power-sharing plan between industries and households can be developed based on TFT predictions. The power-sharing plan may involve a limited power supply on hours that have less usage or a day-wise sharing plan to ration the power supply.

Inconsistent power supply may cause massive economic losses and such events need to be dealt with most robustly. In France, the nuclear power plant for supplying electricity failed and power had to be bought at exorbitant prices from neighbors during the Ukro-Russo War. This import of power was unexpected and the volume to be imported was misjudged. The volume of power to be imported was revised several times and this led to additional costs. Such situations can be averted by the actual load known on different levels of granularity.

Green Energy Policy can be framed by recommending power consumption habits to households based on a shared power community plan, where the generation capacity is in sync with the capacity of electricity consumption. Since the generation of green energy is limited, a community-based power-sharing plan will help suffice energy needs through green energy entirely.

The Temporal Fusion has a variety of use cases for all kinds of datasets, like agriculture where some static and categorical variables like soil quality, soil nutrients, market prices, and weather indicators can be used to predict the ideal harvest time for crops. In manufacturing, the TFT can be used to predict real-time issues with machinery during the actual working of the machinery. Another domain where the use of TFT can prove to be useful in predicting pollution levels.

About Authors

Vedant Ghavate

Vedant has completed his Bachelor of Engineering Degree from Saviritbai Phule Pune University. He has experience working as a freelancer for the digital migration of a business, as an intern for a startup, and as a Business intelligence for a Multinational Company. Currently, he is pursuing his Masters in Big Data Analytics Degree.

Ethan Nyi Nyi

Ethan has completed his Bachelor of Business Administration with Concentrations in Information Systems and Finance from Boston University. He has experience working within the asset management sector as a data analyst, where he specialized in providing solutions for mortgage originations and credit risk modeling. Currently, he is pursuing his Master's in Big Data Analytics at San Diego State University.

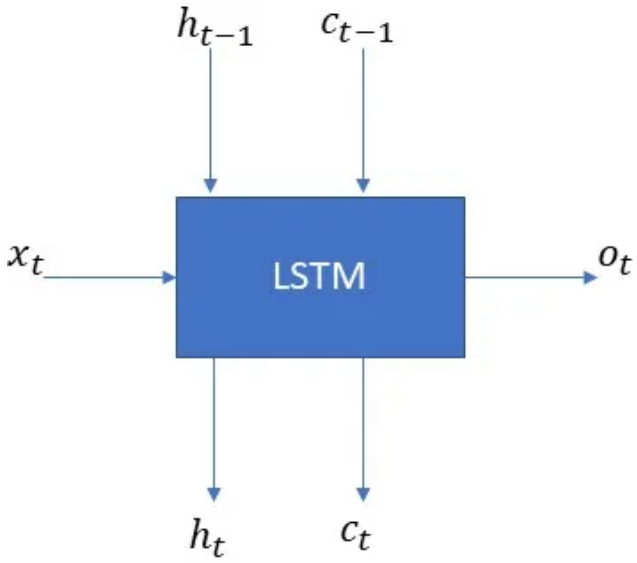
Appendix A

- The power consumption dataset has 25k nan/null values which are interpolated, these null/0.0 values may be due to power failure on the domestic household level such as MCB tripping and overload on the fuse.
- Since the dataset includes data for only one household, we have to take into account the specific power consumption habits of the residents of that particular household (spending weekends away from home, annual vacation).
- Min Max normalization is used for the stacked bar graph
- Standard scalar and robust scalar are used for the overlay chart
- Date start and end are from 1/1/2007 to 11/26/2010 since power consumption data is available only for those values.
- Spline interpolation is used to fill in missing values



σ_g : $sigmoid$
σ_c : tanh
. : element wise multiplication

$$f_t = \sigma_g\,(W_f \times x_t + U_f \times h_{t-1} + b_f)$$
$$i_t = \sigma_g\,(W_i \times x_t + U_i \times h_{t-1} + b_i)$$
$$o_t = \sigma_g\,(W_o \times x_t + U_o \times h_{t-1} + b_o)$$
$$c'_t = \sigma_c\,(W_c \times x_t + U_c \times h_{t-1} + b_c)$$
$$c_t = f_t \cdot c_{t-1} + i_t \cdot c'_t$$
$$h_t = o_t \cdot \sigma_c(c_t)$$

f_t *is the forget gate*
i_t *is the input gate*
o_t *is the output gate*
c_t *is the cell state*
h_t *is the hidden state*

Shown above: The figure shows the input and outputs of an LSTM cell for a single timestep.

  Partial import of sklearn during the build process.
  setup.py:128: DeprecationWarning:

    `numpy.distutils` is deprecated since NumPy 1.23.0, as a result
    of the deprecation of `distutils` itself. It will be removed for
    Python >= 3.12. For older Python versions it will remain present.
    It is recommended to use `setuptools < 60.0` for those Python versions.
    For more details, see:
      https://numpy.org/devdocs/reference/distutils_status_migration.html

    from numpy.distutils.command.build_ext import build_ext  # noqa
